

Figure S4. Bone marrow status after several cycles of carboplatin is compromised. In the first three dosing cycles, both MPP (panel A) and MEP (panel B) experienced great cell loss (around 80-90% of population depletion at nadir), but were able to recover the homeostatic equilibrium, due to negative feedback loops. In our experiments, bone marrow status was not assessed again until the 8th cycle, where full recovery was no more achieved for these two populations, whose observed sizes were around 60% of their baseline values. CMP (panel C), on the other hand, were not able to recover their homeostatic equilibrium from the 1st cycle, resulting in a depletion of around 80% when considering multiple cycles. This highlights the impact of different proliferation rates on the numbers of progenitor cell populations following a prolonged dosing period.
